

## Motivation

- Current **weakly-supervised diffusion models** for anomaly detection is **not fully weakly-supervised**.
  - Pixel-level labels is required for hyperparameter tuning in inference!
  - Subject to human annotator bias
  - Costly
- Current hyperparameter selection is **fixed**
  - All samples are using the same hyperparameters, e.g., noise level and threshold.
- Need a new **dynamical** hyperparameter selection method.
  - Get rid of pixel-level labels
  - Select hyperparameters individually

## Contributions

- A fully weakly-supervised anomaly detection framework
- Novel dynamical threshold and noise scale selection and novel fixed guidance strength selection for diffusion models on weakly-supervised anomaly detection
- Novel aggregation strategy combined with dynamical noise scale selection to enhance the signal strength of anomalous regions on anomaly map

## Method

- No iterative reconstruction
- Only the forward process
  - Healthy guided
  - Unguided
- Aggregate SAMs until  $t_e$ 
  - $t_e$  dynamical noise scale
  - Capture 'sweet spot'
  - Determined by max  $M_t$
- Segmentation threshold  $Q^*$ 
  - Determined by anomaly size
  - Roughly linear related with  $M_{t_e}$
- Optimal fixed guidance strength  $w^*$ 
  - Determined separately according to classification
  - See Sec. 4.2 in our paper

## Sub-anomaly Maps (SAMs)

## Healthy-guided Forward Process (HFP)

## Unguided Forward Process (UFP)

$$\tilde{x}_{0,t}^h = \frac{x_t - \sqrt{1 - \bar{\alpha}_t} [(1 + w)\epsilon_{\theta}(x_t, t, h) - w\epsilon_{\theta}(x_t, t, \emptyset)]}{\sqrt{\bar{\alpha}_t}}$$

$$\tilde{x}_{0,t}^{\emptyset} = \frac{x_t - \sqrt{1 - \bar{\alpha}_t}\epsilon_{\theta}(x_t, t, \emptyset)}{\sqrt{\bar{\alpha}_t}}$$

$$M_t = \frac{\|\tilde{x}_{0,t}^h - \tilde{x}_{0,t}^{\emptyset}\|_2^2}{d}$$

$\frac{B_t^2(1+w)^2}{d} \|\nabla_{x_t} \log p_{\theta}(h|x_t)\|_2^2$

↓

The divergence  $M_{t_e}$  is essentially the magnitude of weighted gradient of the log-likelihood of the implicit classifier

$$e_t^h = \tilde{x}_{0,t}^h - x_0$$

$$S_t = (e_t^h)^2$$

$B_t^2 ((1 + w)\nabla_{x_t} \log p_{\theta}(h|x_t) + \Delta s_t)^2$

↓

SAM has similar form but with an extra error term  $\Delta s_t$ . It achieves better results compared to use the difference between two forward processes.

## How SAMs change?

- Focus: high-frequency to low-frequency components
- The signals from healthy regions appear randomly distributed.
- The signals from anomalous regions exhibit more consistency.
- This consistency is crucial to the effectiveness of the aggregation process.
